Edited by Richard A. Dixon, The Samuel Roberts Noble Foundation, Ardmore, OK, and approved February 22, 2012 (received for review December 6, 2011)

Efficient lignin depolymerization is unique to the wood decay basidiomycetes, collectively referred to as white rot fungi. *Phanerochaete chrysosporium* simultaneously degrades lignin and cellulose, whereas the closely related species, *Cerioporiopsis subvermispora*, also depolymerizes lignin but may do so with relatively little cellulose degradation. To investigate the basis for selective ligninolysis, we conducted comparative genome analysis of *C. subvermispora* and *P. chrysosporium*. Genes encoding manganese peroxidase were number 13 and five in *C. subvermispora* and *P. chrysosporium*, respectively. In addition, the *C. subvermispora* genome contains at least seven genes predicted to encode laccases, whereas the *P. chrysosporium* genome contains none. We also observed expression of the number of *C. subvermispora* desaturase-encoding genes putatively involved in lipid metabolism. Microarray-based transcriptome analysis showed substantial up-regulation of several desaturase and MnP genes in wood-containing medium. MS identified MnP proteins in *C. subvermispora* culture filtrates, but none in *P. chrysosporium* cultures. These results support the importance of MnP and a lignin degradation mechanism whereby cleavage of the dominant nonphenolic structures is mediated by lipoyxidation products. Two *C. subvermispora* genes were predicted to encode peroxidases structurally similar to *P. chrysosporium* lignin peroxidase and, following heterologous expression in *Escherichia coli*, the enzymes were shown to oxidize high redox potential substrates, but not MnP. Apart from oxidative lignin degradation, we also examined cellulolytic and hemicellulolytic systems in both fungi. In summary, the *C. subvermispora* genetic inventory and expression patterns exhibit increased oxidoreductase potential and diminished cellulolytic capability relative to *P. chrysosporium*.

This article is a PNAS Direct Submission.

Data deposition: The annotated genome is available on an interactive web portal, http://jgi.doe.gov/Cerioporiopsis and at DNA Data Base in Japan/European Molecular Biology Laboratory (DDBJ/EMBL/Genbank (project accession no. AEOV00000000). The data reported in this paper have been deposited in the Gene Expression Omnibus (GEO) data-base, www.ncbi.nlm.nih.gov/geo (accession no. GSE34636).

The most abundant source of photosynthetically fixed carbon in land ecosystems is plant biomass, composed primarily of cellulose, hemicellulose, and lignin. Many microorganisms are capable of using cellulose and hemicellulose as carbon and energy sources, but a much smaller group of filamentous fungi in the phylum Basidiomycota has also evolved with the unique ability to efficiently depolymerize and mineralize lignin, the most recalcitrant component of plant cell walls. Collectively known as white rot fungi, they remove lignin to gain access to cell wall carbohydrates for carbon and energy sources. These wood-decay fungi are common inhabitants of fallen trees and forest litter. As such, white rot fungi play a pivotal role in the carbon cycle. Their unique metabolic capabilities are of considerable recent interest in bioenergy-related processes (1).

White rot basidiomycetes differ in their gross morphological patterns of decay (ref. 2 and refs. therein). *Phanerochaete chrysosporium* simultaneously degrades cellulose, hemicellulose, and lignin, whereas a few others such as the closely related polypore species, *Ceriporiopsis subvermispora*, have the ability to remove lignin in advance of cellulose. The mechanistic basis of this selectivity is unknown.

The roles of *P. chrysosporium* lignin peroxidase [LiP; Enzyme Commission (EC) 1.11.1.14] and manganese peroxidase (EC 1.11.1.13) have been intensively studied (3). Reactions catalyzed by LiP include Cα-Cα cleavage of propyl side chains in lignin and lignin models, hydroxylation of benzylic methylene groups, oxidation of benzylic alcohols to the corresponding aldehydes or ketones, phenol oxidation, and aromatic ring cleavage in nonphenolic lignin model compounds. In addition to *P. chrysosporium*, multiple ligninolytic peroxidase isozymes and their corresponding genes have been identified in several efficient lignin-degrading fungi (4). In some white rot fungi, such as the oyster mushroom *Pleurotus ostreatus* and related species, LiP is absent, but a third ligninolytic peroxidase type which combines LiP and MnP catalytic properties, versatile peroxidase (VP; EC 1.11.1.16), has been characterized (4, 5) and identified by genome analysis (6). Repeated and systematic attempts have failed to identify LiP (or VP) activity in *C. subvermispora* cultures, but substantial evidence implicates MnP in linyinolysis (e.g., refs 7, 8). First discovered in *P. chrysosporium* cultures, this enzyme oxidizes Mn²⁺ to Mn³⁺, using H₂O₂ as an oxidant (9, 10). MnP cannot directly cleave the dominant nonphenolic structures within lignin, but it has been suggested that oxidation may be mediated by lipid peroxidation mechanisms that are promoted by Mn³⁺ (3).

In addition to peroxidases, laccases (EC 1.10.3.2) have been identified in *P. chrysosporium* cultures (11). Laccases are involved in lignin degradation. Several have been characterized from *C. subvermispora* cultures (11), whereas no genes encoding laccase, in the strict sense, are present in the *P. chrysosporium* genome (12). The mechanism by which laccases might degrade lignin remains unclear, as the enzyme lacks sufficient oxidation potential to cleave nonphenolic linkages within the polymer. However, various mediators have been proposed (13).

Other components commonly ascribed to ligninolytic systems include extracellular enzymes capable of generating hydrogen peroxide. Glucose–methylcholine oxidoreductases such as aryl-alcohol oxidase, methanol oxidase and pyranose oxidase, together with copper radical oxidases such as glyoxal oxidase, aryl-alcohol oxidase, methanol oxidase and pyranose oxidase, have been characterized in *P. chrysosporium* (14), but none of these activities have been reported in *C. subvermispora* cultures. Conceivably, selective lignin degradation patterns may involve modulation of the hydrolytic enzymes commonly associated with cellulose and hemicellulose degradation. These systems are well suited to degradation in *P. chrysosporium*, whereas little is known about *C. subvermispora* glycoside hydrolases (GHs) (15).

To further our understanding of selective ligninolysis, we report here initial analysis of the *C. subvermispora* genome. Comparison with the genome, transcriptome, and secretome of *P. chrysosporium* reveal substantial differences among the genes that are likely to be involved in lignocellulose degradation, providing insight into diversification of the white rot mechanism.
**Peroxidases.** Twenty-six *C. subvermispora* gene models are predicted to encode heme peroxidases. Fifteen were classified as probable ligninolytic peroxidases, which included 13 MnPs, a VP, and an LiP. These classifications were based on homology modeling (18) with particular attention to conserved Mn$^{2+}$ oxidation and catalytic tryptophan sites (19, 20). Those classified as MnPs include seven typical “long” MnPs specific for Mn$^{2+}$, and a “short” MnP also able to oxidize phenols and 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonate) in the absence of Mn$^{2+}$, as previously reported in the *P. ostreatus* genome (6). The remaining five could be classified as “extra long” MnPs in view of their long C-termini, as reported for the first time in *Dichomitus squalens* MnPs (21). Only four full-length MnP-encoding genes were previously identified in *C. subvermispora* (GenBank accession nos. AAB03480, AAB92247, AAO61784, and AF161585). Additional class II peroxidases have long been suspected (22, 23), but no LiP/VP-like transcripts or activities have been identified. Thus, the repertoire of *C. subvermispora* peroxidases differs from *P. chrysosporium*, which features 10 LiP and five MnP genes (Fig. 1). Extending comparative analysis to 90 basidiomycete peroxidases (SI Appendix, Fig. S3) suggested that the *C. subvermispora* VP and LiP represent divergent proteins, an observation consistent with their catalytic properties (as detailed later).

By using a previously developed *Esherichia coli* expression system including in vitro activation (24, 25), the *C. subvermispora* putative LiP (Cesubv118677) and VP (Cesubv99382) were evaluated for their oxidation of three representative substrates, namely Mn$^{2+}$, the high redox-potential veratryl alcohol (VA), and Reactive Black 5 (RBS) (Table 1). The corresponding steady-state kinetic constants were compared with those of *Pleurotus eryngii* VP (isozyme VPL; AF007244), a *P. chrysosporium* LiP (isozyme H8; GenBank accession no. Y00262), and a conventional *C. subvermispora* MnP (Cesubv117436; Fig. 1) also produced in *E. coli*. The putative *C. subvermispora* LiP (protein model Cesubv118677) was unable to oxidize Mn$^{2+}$ as expected given the absence of a typical manganese oxidation site in its theoretical molecular structure (SI Appendix, Fig. S2). A conventional *C. subvermispora* MnP protein (Cesubv117436), also predicted based on structure, and the VP from *P. eryngii* showed Mn$^{2+}$ oxidation. Surprisingly, the *C. subvermispora* protein designated Cesubv99382, which we tentatively classified as a VP, was not able to oxidize Mn$^{2+}$, irrespective of the presence of a putative manganese oxidation site in its structural model (SI Appendix, Fig. S2). The catalytic behaviors of Cesubv99382 and Cesubv118677 are very similar. Both enzymes oxidize VA, the typical LiP (and VP) substrate, and also RBS, a characteristic substrate of VP (that LiP is unable to oxidize in the absence of mediators), with similar $K_{\text{m}, \text{LiP}}$, $K_{\text{c,a}}$, and $k_{\text{cat}}/K_{\text{m}, \text{LiP}}$ values (Table 1).

Peroxidase expression patterns differed significantly between *C. subvermispora* and *P. chrysosporium*. In medium containing ball-milled *Populus grandidentata* (aspen) as sole carbon source, transcript levels of two *C. subvermispora* MnPs were significantly up-regulated relative to glucose medium. Liquid chromatography/tandem MS (LC-MS/MS) analysis of culture filtrates identified peptides corresponding to three *C. subvermispora* MnP genes (Fig. 1). In identical media, none of the *P. chrysosporium* MnP genes were up-regulated, but significant accumulation of two LiP gene transcripts was observed relative to glucose (Fig. 1). No peroxidases were identified by LC-MS/MS analysis of *P. chrysosporium* culture filtrates.

**Multicopper Oxidases.** Nine multicopper (MCO)-encoding *C. subvermispora* genes may be relevant to lignin degradation. Multiple alignments emphasizing signature regions (26, 27) revealed the presence of seven laccases, in the strictest sense, one of which was previously known (28). This observation is in distinct contrast to the *P. chrysosporium* genome, which contains no laccases (12) (Fig. 2). Consistent with a role in lignocellulose modification, transcript levels corresponding to *C. subvermispora* laccase was significantly up-regulated (more than threefold; $P < 0.01$) in media containing ball-milled *P. grandidentata* wood (aspen) relative to glucose medium (Fig. 2).

In addition to the laccases, *C. subvermispora* MCO-encoding genes included a canonical ferroxidase (Fet3). Involved in high-affinity iron uptake, the Fet3 genes of *C. subvermispora* (Cesubv67172) and *Postia placenta* (Posp129808) show significant up-regulation on aspen-containing medium, whereas the *P. chrysosporium* orthologue (Pchhr26890) is sharply down-regulated under identical conditions (Fig. 2). This strongly suggests that iron homeostasis is achieved by different mechanisms in these fungi.

**Other Enzymes Potentially Involved in Extracellular Redox Processes.** Peroxide and free radical generation are considered key components of ligninolysis, and analysis of the *C. subvermispora* genome, transcriptome, and secretome revealed a diverse array of relevant proteins. These included four copper radical oxidases, cellobiose dehydrogenase, various other glucose–methanol–choline oxidoreductases, and several putative transporters. Possibly related to selectivity of ligninolysis, expression patterns exhibited by certain genes, e.g., methanol oxidase, differed significantly between *P. chrysosporium* and *C. subvermispora*. (SI Appendix and SI Appendix, Table S1, include detailed listings of all annotated genes, transcript levels, and LC-MS/MS identification of extracellular proteins.)

Of particular relevance to lignin degradation by MnP, we observed a significant expansion of the genes putatively involved in fatty acid metabolism (Table 2). Relative to the single gene in *P. chrysosporium* (encoding Pchhr125220) the Δ-12 fatty acid desaturase gene family was particularly expanded (five paralogues) in *C. subvermispora*. The *P. chrysosporium* and *C. subvermispora*
by using RAxML with the WAG substitution matrix, P. chrysosporium accession no. GSE14736 (33) for scripts in BMA relative to glucose-grown (Glc) cultures was determined using the Moderated structures of lignin.

Increased numbers of MnP and lipid metabolism genes, viewed (Cesubv117066) in aspen wood media relative to glucose media. Under identical conditions, accumulating P. chrysosporium transcripts included four GH7 cellobiohydrolases, two GH5 endo-1,4-glucosidases, and a GH12 endoglucanase (Table 3), which 18 and three, respectively, corresponded to GHs.

Genes encoding likely cellulases showed only modest transcript levels in C. subvermispora (Table 3). C. subvermispora transcripts corresponding to single copies of a CBM1-containing cellobiohydrolase (GH7), a CBM1-containing endo-β-1,4-glucanase (GH5), and a GH12 endoglucanase, all canonical cellulases, were significantly up-regulated (more than twofold; P < 0.01) in aspen wood relative to glucose media. Under identical conditions, accumulating P. chrysosporium transcripts included four GH7 cellobiohydrolases, two GH5 endo-1,4-glucanases, and two GH12 endoglucanases (Table 3).

The foregoing analysis is limited to expression patterns of genes with putative function inferred from sequence comparisons. However, many of the predicted proteins that show no significant sequence similarity to known proteins could be important in selective ligninolysis. Specifically, we identified 139 “hypothetical” C. subvermispora proteins whose sequences show no significant similarity to known proteins.

Normalized microarray data are presented as log2 signal strength average of fully replicated experiments. Significant accumulation (B/G ratio) of transcripts in BMA relative to glucose-grown (Glc) cultures was determined using the Moderated t test and associated FDR. See Gene Expression Omnibus accession no. GSE147336 (33) for P. chrysosporium data. Both gene families are expanded in C. subvermispora relative to P. chrysosporium. BMA, ball-milled aspen; COG, clusters of orthologous groups; FDR, false detection rate.

*Significant ratio (≤0.5-fold to ≥2-fold).

Carbohydrate Active Enzymes. Overall, the number of GHs encoded by the C. subvermispora genome is slightly lower than that of other plant cell wall degrading basidiomycetes whose genomes have been sequenced (Dataset SI and SI Appendix; Table S1). The number of GHs in C. subvermispora (n = 171) is close to that in P. chrysosporium (n = 177), and noticeably different in total number and in family distribution compared with the phylogenetically related brown rot fungus P. placenta (n = 145; Fig. 3). Differences between C. subvermispora and P. chrysosporium are limited to a few families, but these distinctions might have consequences for degradation of plant cell wall polysaccharides. For example, C. subvermispora contained only three predicted proteins belonging to family GH7, an important group typically featuring “exo” cellobiohydrolases. In contrast, at least six GH7 protein models were identified in the P. chrysosporium genome. Family GH3, containing β-glucosidases involved in the hydrolysis of cellobiose, was represented by only six gene models in the C. subvermispora genome, unlike the 11 GH3 models found in P. chrysosporium. In addition, the C. subvermispora genome revealed only 16 cellulose binding modules (CBM1s), compared with 31 CBM1-containing protein models found in the P. chrysosporium genome.

In contrast to the oxidative systems, transcriptome and secretome analysis of GHs generally showed lower expression in C. subvermispora relative to P. chrysosporium (Table 3 and SI Appendix, Table S1). Transcripts corresponding to 30 C. subvermispora GH-encoding genes accumulated more than twofold (P < 0.05) in aspen wood- vs. glucose-containing media. In contrast, 52 P. chrysosporium GH-encoding genes were up-regulated (more than twofold; P < 0.05). MS unambiguously identified 60 and 121 proteins in filtrates from aspen wood media of P. chrysosporium and C. subvermispora cultures, respectively, among which 18 and three, respectively, corresponded to GHs.

Genes encoding likely cellulases showed only modest transcript levels in C. subvermispora (Table 3). C. subvermispora transcripts corresponding to single copies of a CBM1-containing cellobiohydrolase (GH7), a CBM1-containing endo-β-1,4-glucanase (GH5), and a GH12 endoglucanase, all canonical cellulases, were significantly up-regulated (more than twofold; P < 0.01) in aspen wood relative to glucose media. Under identical conditions, accumulating P. chrysosporium transcripts included four GH7 cellobiohydrolases, two GH5 endo-1,4-glucanases, and two GH12 endoglucanases (Table 3).
no significant similarity to *P. chrysosporium* models but were otherwise highly expressed, i.e., transcript levels more than two SDs above the genome-wide mean (n = 12084, X = 10.56) or more than twofold transcript accumulation in aspen wood media vs. glucose or unambiguously identified via MS (at least two unique peptide sequences).

**Discussion**

*C. subvermispora* and *P. chrysosporium* are both members of the order Polyporales, but they differ sharply in their ability to selectively degrade lignin. The genetics and physiology of *P. chrysosporium* have been intensively studied for decades. Largely because of its efficient degradation of plant cell walls, including the recalcitrant lignin, *P. chrysosporium* was selected as the first sequenced basidiomycete (12). In contrast, *C. subvermispora* has received less attention, although its selective lignin degradation is well known (2). Overall, our comparisons of *C. subvermispora* and *P. chrysosporium* gene repertoires, together with expression patterns on a complex lignocellulose substrate, suggest divergent strategies of plant cell wall degradation and provide clues about mechanisms of selective delignification.

Generally accepted as important components of lignin degradation systems, class II peroxidases were skewed toward expansion of the number of MnPs and accompanied by a putative LiP (Cesuvb118677) and a VP (Cesuvb99382). To confirm these predictions, both peroxidases were obtained by *E. coli* expression, and their steady-state kinetic constants for oxidation of selected peroxidase substrates were compared with those of a typical MnP from the *C. subvermispora* genome (Cesuvb117436), a well characterized VP from *P. eryngii* (GenBank AF007244), and the well studied *P. chrysosporium* LiP isozyme H8 (all expressed in *E. coli*). Cesuvb118677 and Cesuvb99382 are able to directly oxidize 4-VA and RB5, a unique characteristic of VP, exhibiting similar catalytic efficiency values to those observed for typical VPs. Moreover, both peroxidases are unable to oxidize Mn2+, despite the presence in Cesuvb99382 of a putative oxidation site for this cation. Thus, considering their sequences (Fig. 1 and SI Appendix) and catalytic activities (Table 1), these two peroxidases seem to represent an intermediate evolutionary state between LiP and VP.

In addition to the distinct repertoire of class II peroxidases, selective ligninolysis of *C. subvermispora* may be related, in part, to the expansion and coexpression of the genes putatively involved in lipid metabolism. Substantial evidence implicates MnP involvement (7, 8) in lignin degradation, but this enzyme cannot directly cleave the dominant nonphenolic structures within lignin. Nevertheless, several studies support mechanisms involving peroxidation of lipids (3). The expansion of *C. subvermispora* desaturase and MnP gene families, together with their high ex-
pression levels relative to *P. chrysosporium* (Table 2 and Fig. 1), are consistent with a role in lignin degradation.

Overall numbers and family distributions of GH-encoding genes were similar between *C. subvermispora* and *P. chrysosporium* (Fig. 3), but subtle differences in number and expression were noted. Among the cellulases, cellobiohydrolases (*cel7s*) and endoglucanases (*cel15s* and *cel12s*) were particularly notable in their transcript and protein accumulation in *P. chrysosporium* cultures (Table 3). In contrast, expression of the *C. subvermispora* cellulolytic system was substantially lower than *P. chrysosporium*, whereas the converse was observed for enzymes important in extracellular oxidative systems (Figs. 1 and 2, Table 2, and SI Appendix, Table S1).

These observations provide functional models that may explain the shift toward selective ligninolysis by *C. subvermispora*. Definitive mechanisms remain uncertain, but our investigations identify a subset of potentially important genes, including those encoding hypothetical proteins. More detailed functional analysis is complicated by the insoluble nature of lignocellulose substrates and by the slow, asynchronous hyphal growth of lignin degrading fungi. Direct and persuasive proof of gene function would be aided by development of experimental tools such as gene disruption/suppression or isoform-specific immunolocalization of secreted proteins.

**Methods**

**Genome Sequencing, Annotation, and Archival.** A whole genome shotgun approach was used to sequence *C. subvermispora* monokaryotic strain B (16) (US Department of Agriculture Forest Mycology Center, Madison, WI). Assembly and annotations are available through interactive visualization and analysis tools from the Joint Genome Institute genome portal (http://www.jgi.doe.gov/Ceriporiopsis) and at DNA Data Base in Japan/European Molecular Biology Laboratory/GenBank under project accession no. AEOV00000000. Details regarding the assembly, repetitive elements (Dataset S2), ESTs annotation, and specific gene sets are provided separately (SI Appendix, Figs. S1–S6).

**MS.** Soluble extracellular proteins were concentrated from *C. subvermispora* cultures containing ball-milled aspen as previously described for *P. chrysosporium* (31) This medium allows rapid growth on a lignocellulose substrate more relevant than glucose- or cellulose-containing media. However, the milling process pulverizes wood cell walls and the culture conditions may not replicate “natural” decay processes. Sample preparation and nano-LC-MS/MS analyses were performed as described in SI Appendix. Peptides were identified using a Mascot search engine (Matrix Science) against protein sequences of 12,125 predicted gene models described earlier. Complete listings of carbohydrate active enzymes and oxidative enzymes, including peptide sequences and scores, are provided in SI Appendix, Table S1.

**Expression Microarrays.** NimbleGen arrays (Roche) were designed to assess expression of 12,084 genes during growth on ball-milled aspen (P. grandidentata) or on glucose as sole carbon sources. Methods are detailed in SI Appendix, and all data deposited under accession no. GSE34636.

**ACKNOWLEDGMENTS.** We thank Sally Ralph (Forest Products Laboratory) for preparation of ball-milled wood. The major portions of this work were performed under US Department of Agriculture Cooperative Research, Education, and Extension Service Grant 2007-35504-18257 (to D.C. and R.A.B.). The US Department of Energy Joint Genome Institute is supported by the Office of Science of the US Department of Energy under Contract DE-AC02-05CH11231. This work was supported by Spanish Projects BIO2008-01533 and BIO2011-26694, European Project Peroxidases as Biocatalysts KBBE-2010-4-265397 (to F.J.-R.D. and A.T.M.), the Chilean National Fund for Scientific and Technological Development Grant 1090513 (to L.F.L.), and a “Ramon y Cajal” contract (to F.J.-R.D.).

**Supplemental Material**

6. Kersten P, Cullen D (2007) Extracellular oxidative systems of the lignin-degrading fungus *C. subvermispora*. A whole genome shotgun approach was used to sequence *C. subvermispora* monokaryotic strain B (16) (US Department of Agriculture Forest Mycology Center, Madison, WI). Assembly and annotations are available through interactive visualization and analysis tools from the Joint Genome Institute genome portal (http://www.jgi.doe.gov/Ceriporiopsis) and at DNA Data Base in Japan/European Molecular Biology Laboratory/GenBank under project accession no. AEOV00000000. Details regarding the assembly, repetitive elements (Dataset S2), ESTs annotation, and specific gene sets are provided separately (SI Appendix, Figs. S1–S6).

**MS.** Soluble extracellular proteins were concentrated from *C. subvermispora* cultures containing ball-milled aspen as previously described for *P. chrysosporium* (31) This medium allows rapid growth on a lignocellulose substrate more relevant than glucose- or cellulose-containing media. However, the milling process pulverizes wood cell walls and the culture conditions may not replicate “natural” decay processes. Sample preparation and nano-LC-MS/MS analyses were performed as described in SI Appendix. Peptides were identified using a Mascot search engine (Matrix Science) against protein sequences of 12,125 predicted gene models described earlier. Complete listings of carbohydrate active enzymes and oxidative enzymes, including peptide sequences and scores, are provided in SI Appendix, Table S1.

**Expression Microarrays.** NimbleGen arrays (Roche) were designed to assess expression of 12,084 genes during growth on ball-milled aspen (P. grandidentata) or on glucose as sole carbon sources. Methods are detailed in SI Appendix, and all data deposited under accession no. GSE34636.

**ACKNOWLEDGMENTS.** We thank Sally Ralph (Forest Products Laboratory) for preparation of ball-milled wood. The major portions of this work were performed under US Department of Agriculture Cooperative Research, Education, and Extension Service Grant 2007-35504-18257 (to D.C. and R.A.B.).
